# **Programming Languages**

Memory Allocation, Garbage Collection

CSCI.GA-2110-001 Fall 2013

# Dynamic memory management

For most languages, the amount of memory used by a program cannot be determined at compile time

earlier versions of FORTRAN are exceptions!

Some features that require dynamic memory allocation:

- recursion
- pointers, explicit allocation (e.g., new)
- higher order functions

## **Types of Allocation**

- Static absolute address retained throughout program's execution.
  - Static variables
  - ◆ Global variables
  - Certain fixed data (e.g., string literals, constants)
- Stack last-in, first-out (LIFO) ordering.
  - Subroutine arguments
  - Local variables
  - Runtime system data structures (displays, etc.)
- Heap general storage, for allocation at arbitary times.
  - Explicitly or automatically allocated
  - Resizable types (e.g., String)
  - Java class instances
  - ◆ All objects and data structures in Python

The heap is finite – if we allocate too much space, we will run out.

Solution: deallocate space when it is no longer necessary.

Methods:

- Manual deallocation, with e.g., free, delete (C, Pascal)
- Automatic deallocation via garbage collection (Java, C#, Scheme, ML, Perl)
- $\blacksquare$  Semi-automatic deallocation, using destructors (C++, Ada)
  - Automatic because the destructor is called at certain points automatically
  - ◆ Manual because the programmer writes the code for the destructor

Manual deallocation is dangerous (because not all current references to an object may be visible).

Foo\* f = new Foo;

Most languages permit custom memory allocation/deallocation. Some permit overloading the allocation/deallocation operators (new, delete, etc.). in C++: class Foo { // data members here public: static void\* operator new (unsigned int num\_bytes) {} static void operator delete(void\* p) {} **}**; Usage:

Programming language C contains a library of helpful memory functions:

- 1. malloc: allocate memory from the heap.
- 2. alloca: allocates memory from the stack. Automatically freed.
- 3. calloc: allocate zero-initialized memory from the heap.
- 4. realloc: increases the size of an already allocated block.

Use free to deallocate memory allocated above (except alloca).

Control over allocation is essential in some applications.

Object *construction* often accompanies allocation. C++ example:

Foo myArray[250]; // allocate and call constructor 250 times.

Sometimes we can't afford to slow down the program like this. Also, C++ won't let us use anything but a default constructor.

Solution: allocate the memory now, construct objects later.

```
Foo* myArray = (Foo*)malloc(sizeof(Foo)*250);
...
new (myArray+x) Foo(); // invoke constructor at myArray[x]
```

This is called *placement-new*. Any constructor can be called (not just default). Call be invoked again at any time without deallocating/allocating memory.

## **Allocation Methods**

#### Two basic methods:

- free list typically for manual and semi-automatic deallocation
- heap pointer typically for automatic deallocation

#### Free list method:

- a linked list of unused blocks of memory is maintained (the free list)
- Allocation: a search is done to find a free block of adequate size; it's removed from the free list
  - first-fit, best-fit
- **Deallocation**: the block is placed on the free list

#### Problems:

- may take some time to find a free block of the right size
- memory eventually becomes fragmented

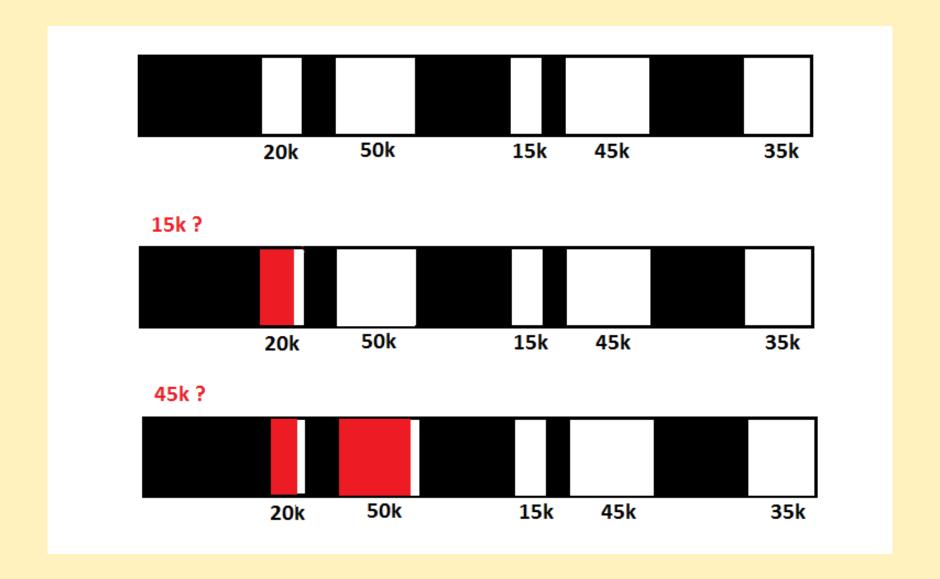

## **Allocation Methods**

- First fit: select the first block large enough to satisfy the request.
- Best fit: select the *smallest* block large enough to satisfy the request.

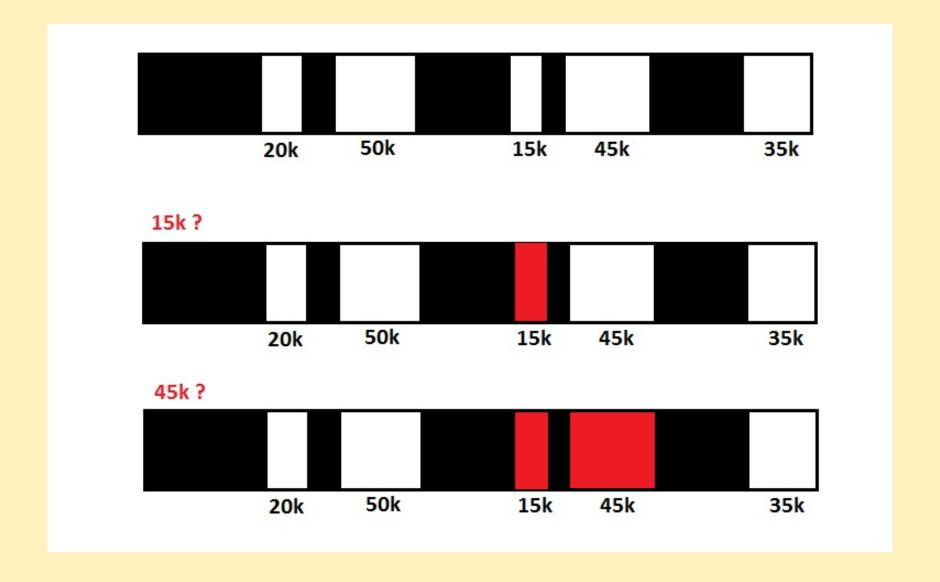

### Both suffer from fragmentation:

- Internal fragmentation: memory allocated but not used.
- External fragmentation: memory not allocated, but too small to be used.

## First Fit

## **Best Fit**

## Allocation: Heap pointer

### **Heap pointer method**:

- initially, the heap pointer is set to bottom of heap
- Allocation: the heap pointer is incremented an appropriate amount
- **Deallocation**: defragmentation eventually required

#### Problems:

requires moving live objects in memory

## **Automatic deallocation**

An automatically deallocated language is said to be garbage collected.

What languages use this?

- All functional languages (Lisp, ML, Scheme, etc.)
- Modula-3
- Eiffel
- Ruby
- Java
- JavaScript
- .NET ("managed" languages)

Even languages that don't natively support garbage collection can be garbage collected (e.g., C++).

## **Automatic deallocation**

Basic garbage collection algorithms:

- mark/sweep needs run-time support
  - variant: compacting
  - variant: non-recursive
- copying needs run-time support
  - variant: incremental
  - variant: generational
- reference counting usually done by programmer

# Mark/sweep & Copying GC

An object x is *live* (i.e., can be referenced) if:

- x is pointed to by some variable located
  - on the stack (e.g., in an activation record)
  - in static memory
- there is a register (containing a temporary or intermediate value) that points to x
- there is another object on the heap (e.g., y) that is live and points to x

All live objects in the heap can be found by a graph traversal:

- start at the *roots* local variables on the stack, static memory, registers.
- any object not reachable from the roots is dead and can be reclaimed

# Mark/sweep

- each object has an extra bit called the mark bit
- mark phase: the collector traverses the heap and sets the mark bit of each object encountered
- **sweep phase**: each object whose mark bit is not set goes on the free list

name	definition
GC()	<pre>for each root pointer p do     mark(p); sweep();</pre>
mark(p)	<pre>if p-&gt;mark /= 1 then p-&gt;mark = 1; for each pointer field p-&gt;x do     mark(p-&gt;x);</pre>
sweep()	<pre>for each object x in heap do   if x.mark = 0 then insert(x, free_list);        else x.mark = 0;</pre>

# Copying

- heap is split into 2 parts: **FROM** space, and **TO** space
- objects allocated in FROM space
- when **FROM** space is full, garbage collection begins
- during traversal, each encountered object is copied to **TO** space
- when traversal is done, all live objects are in **TO** space
- now we flip the spaces **FROM** space becomes **TO** space and vice versa
- Note: since we are moving objects, any pointers to them must be updated. This is done by leaving a *forwarding address*

heap pointer method used for allocation – fast

# Copying

name	definition
GC()	<pre>for each root pointer p do    p := traverse(p);</pre>
traverse(p)	<pre>if *p contains forwarding address then    p := *p; // follow forwarding address    return p; else {    new_p := copy (p, TO_SPACE);    *p := new_p; // write forwarding address    for each pointer field p-&gt;x do         new_p-&gt;x := traverse(p-&gt;x);    return new_p; }</pre>

### **Generational GC**

- a variant of a copying garbage collector
- Observation: the older an object gets, the longer it is expected to stay around.

Why?

- many objects are very short-lived (e.g., intermediate values)
- objects that live for a long time tend to make up central data structures in the program, and will probably be live until the end of the program
- Idea: instead of 2 heaps, use many heaps, one for each "generation"
  - younger generations collected more frequently than older generations (because younger generations will have more garbage to collect)
  - when a generation is traversed, live objects are copied to the next-older generation
  - when a generation fills up, we garbage collect it

## Reference Counting

### The problem:

- we have several references to some data on the heap
- we want to release the memory when there are no more references to it
- may not have "built-in" garbage collection

**Idea**: Keep track of how many references point to the data, and free it when there are no more.

- set reference count to 1 for newly created objects
- increment reference count whenever we make a copy of a pointer to the object
- decrement reference count whenever a pointer to the object goes out of scope or stops pointing to the object
- when an object's reference count becomes 0, we can free it

## Reference Counting

### Advantages:

- Memory can be reclaimed as soon as no longer needed.
- Simple, can be done by the programmer for languages not supporting GC.

### Disadvantages:

- Additional space needed for the reference count.
- Will not reclaim circular references.
- Can be inefficient (e.g., if many objects are reclaimed at once).

# Why reference counting is slow

Consider this seemingly innocuous code:

```
ptr2 = ptr1
```

Look at all the events required just to do this:

- 1. Lock ptr2 (possible contention).
- 2. Decrement old.
- 3. Test old against 0.
- 4. Possible deletion.
- 5. Unlock ptr2.
- 6. Lock ptr1 (possible contention).
- 7. Increment new.
- 8. Unlock ptr1.

## C++: important lifetime events

```
Event what gets called (declaration)

Creation C (...) // constructors

Pass by value C (const C&) // copy constructor

Assignment C& operator= (const C&)

Destruction ~C () // destructor
```

A chief reason C++ has destructors is to enable implementation of *reference* counting.

## Reference Counting: Example

```
class C {
public:
   C () : p(NULL) { }
   C (const C& c) : p(c.p) { if (p) p->refCount++; }
   ^{\sim}C () { if (p && --p->refCount == 0) delete p; }
   C& operator = (const C&);
   . . .
private:
   struct RefCounted {
      int refCount;
      RefCounted (...): refCount(1), ... { ... }
   };
   RefCounted *p;
```

## Reference Counting: assignment

```
const C& C::operator = (const C& c) {
  if (c.p)
     c.p->refCount++;

  if (p && --p->refCount == 0) delete p;

  p = c.p;

  return *this;
}
```

## Conservative collection

- What about weakly typed languages?
- What about languages not designed for GC? (hostile environments)

It turns out that strong typing is not necessary for garbage collection.

**Approach:** traverse the stack, static memory, heap and *guess* whether bit patterns "look like" a pointer.

- If memory beginning at address x was previously allocated and there is no pointer-like memory address pointing to x, then deallocate the block at x.
- If some bit pattern in memory points to x, do not deallocate x.
- Worst case: some objects may not be deallocated.
